Constructing Advantage: Wins/Losses and Probabilities

Daniel H. "Dan" Miller dhmmhd@yahoo.com

> Presented at: AAII Options San Diego, CA

Jul 27, 2019

Trading Advantage: Motivation

- Goal: Develop a **likely** profitable trading strategy.
- Strategy: Balance dollar reward/risk (win/loss) ratio with probability of win in trades.
- Tactics: Be able to reproduce trades in such a system easily and effectively.

Trading Advantage: Basic Idea

- Enter a trade if the *marketplace* probability of winning is greater than a *theoretical* value probability of winning.
- Theoretical value of probability of winning is based on Advantage math model.

Trading Advantage: Method Overview

- Given a trade's *dollar* win / loss ratio,
 compute the corresponding *minimum* corresponding probability of win required.
- Compare *computed model* required minimum probability of win with *marketplace* probability of win.
- If the marketplace probability of win *is greater* than the computed model required probability of win, take the trade.

Example: Basis for Demonstration

- A few examples are used to illustrate Advantage trading theory.
- Different aspects of the trades are highlighted, to understand the approach from beginning to end.
- Other defined-risk option trades can be analyzed using the same method as the provided examples.
- All examples are based on the ThinkOrSwim (ToS) platform. Other platforms can be used, if the necessary data can be extracted from the platform.

Trade Systems vs. Individual Trades (1)

- Trade system
 - Trade system is composed of a **sequence** of trades
 - Each component trade is performed using repeatable and defined rules
 - From initial equity, profit and losses are **accumulated**, resulting in a trade system's *equity curve*
- Trade system equity curve may terminate in different locations, compared to initial equity
 - Break-Even: Equity curve ends near where it began
 - **Profitable**: Equity curve end **above** where it began
 - Losing: Equity curve ends below where it began
- Trade system equity **path** will vary (profit vs. loss)

Trade Systems vs. Individual Trades (2)

- Individual Trades
 - Individual trades are **constructed** to adhere to repeatable and defined trading rules.
 - Individual trades with options can be structured at opening to have *defined win / loss ratio*.
 - Marketplace, however, is probabilistic, so the probability of win (and thus loss) are dynamic.

Equity Curve: Definitions

- Trading System Equity Curve: Profit and loss value of account, over time and over large sequence of trades
- Attributes of equity curve
 - Number of trades, is composed (only) of
 - number of trades that profited
 - number of trades that lost
 - **Dollar** quantities, is composed (only) of
 - total dollar winnings
 - total dollar losses
- Probability of Winning is Number of Trades that Profited *divided* by Total Number of Trades
- Win / Loss Ratio is Total Dollar Winnings divided by Total Dollar Losses

Equity Curves: Aim

- Use **simulation** to evaluate possible equity curves.
- In the simulation of equity curves
 - All trades have the same win / loss ratio (reward / risk ratio).
 - Probability of win is **varied**.
- With the right combinations of win / loss ratios and probabilities of winning, equity curves are more likely to be profitable.
- Simulated equity curves involve probabilities of winning and losing, thus are **not** guaranteed.

Equity Curves: Right Combinations

- Intermediate Win /
- Loss Prob. Equity Curve

Advantage Ratio of Win Losses Ending Equity Curve Value

No	0.66	57%	All	All Lose
No	0.66	60%	About 1/2	Some Lose, Some Gain
No	0.66	61%	About 1/2	Mostly Gain
Yes	0.66	62%	About ¹ / ₄	All Gain
Yes+	0.66	63%	About 1/3	All But 1 Gain

- Each simulated equity curve is 100's of trades.
- Each simulation consists of 10 equity curves.
- Same win/loss ratio in all simulations.
- Five **different** probabilities of win are simulated. 10

From Equity Curves to Trades

Compare:

Use win / loss ratio and probability of winning to **analyze** a prior system,

to:

Construct trades with higher likelihood to grow the equity curve with each *trade*.

Example: Trade Structure

- SPY @ 148.20 on Sept 10, 2007
- Out-of-the-Money bear call vertical, Oct 2007 expiration, \$0.40 credit
 - Sell 150 Call
 - Buy 151 Call
- Key attributes of vertical necessary for Advantage analysis
 - **Defined** win: net option credit
 - Defined loss: difference between strikes less credit
 - Defined probability of win: making 1 cent or more by expiration

Example: Right Combinations

- In General: How can the correct balance between win / loss ratio and probability of win be calculated?
- Specifically: How did I decide to open the trade on the prior slide?
- By constructing each trade with the correct balance between win / loss ratio and probability of win, we aim for a higher likelihood that the equity curve created will terminate with an account value greater than the starting value.

Advantage Formula: Background

Formula: (TW - TL) / TL = C

where

- TW = Total winnings,
- TL = Total losses,
- C = "Advantage" preference

English: A trading system is measured by its winnings in excess of losses, normalized by losses. The *Advantage* measure "C" is a trader's economic preference.

Key: When C=0, there is **equilibrium** between winning and losing: TW = TL

Adapted from David Sepiashvili, *How to Best Evaluate System Performance*, Futures, March 2005

Advantage Formula: Daily Use

• Evaluate **individual** trades using Advantage math:

Probability of Win = S / (1+S)

- A trading system with *positive* advantage (C>0) will *more likely* have a profitable equity curve.
- Henceforth: Advantage = C = 0.1

Advantage Formula: Graphical View

0.698088. 1.45041

19

Probabilities: Needed vs. Marketplace

- Needed probabilities
 - Calculated per the Advantage formula
 - Dependent *only* on win, loss, and C
 - Consequently, needed probabilities are computed *independent* of real-world conditions
 - Marketplace probabilities
 - Valued *real time* in the marketplace
 - Dependent on *time* to expiration

Probabilities: Needed vs. Market

- Opportunity: Given a fixed win / loss ratio and a fixed Advantage (C), the *formula* probability of winning is **different** from *marketplace* probability of winning.
- Probabilities in the marketplace greater than probabilities using the formula indicate trades to open:

Advantage Ratio =

$$\frac{(Probability of Win)_{Marketplace}}{(Probability of Win)_{Formula}} \ge 1$$

Example: Worksheet (revisit)

- SPY @ 148.20 on Sept 10, 2007
- **Decide**: Sell bear vertical, 150/151, Oct07, calls, for \$0.40?

• Formula:

Win / Loss = 40 / 60 = 0.66S = (0.1 + 1) * (60 / 40) = 1.65Probability of Win **Needed** = S / (1 + S) = 0.6226

Probability of Win in *Marketplace* = 0.6374

Advantage Ratio = Probability *Marketplace* / Probability *Needed* = 0.6374 / 0.6226 = **1.02**

• **Conclusion**: *Take* the trade, because Advantage Ratio is *greater* than 1.00

Finding Real World Trades

- Finding real-world Advantaged trade is difficult and relatively rare.
- If such trades exist, they are likely
 - further out in **time**: greater option time value
 - to have higher volatilities: higher volatility means higher prices.

Iron Condor: Worksheet

QQQQ @ 48.20 on Sept 10, 2007

Decide: Sell narrow Iron Condor, 46/47/49/50, Nov07, for \$0.81?

Win / Loss = 81 / 19 = 4.26

S = (0.1 + 1) * (19 / 81) = 0.2580

Probability of Win Needed = S / (1 + S) = 0.2051

Probability of Win in Marketplace =
0.2311

Advantage Ratio =

Probability Marketplace / Probability Needed = 0.2311 / 0.2051 = 1.12

Conclusion: Take the trade

ThinkOrSwim: Tooling

- Find Advantage trades: ToS | Scan | Spread Hacker (Beware: Valid only during market hours)
- Add spread filters for criteria needed for Advantage calculation (ex.: given PoP, compute market W/L ratio)
 - Single expiration date (use +/- 1 for min/max range)
 - "Probability of profit" [probability of win]: Select a specific probability of profit, by bracketing +/- 1 for min/max range
 - "Max profit" [win / loss ratio]: Calculate max profit target using Advantage formula, and use it as minimum of range
- Right click to "Analyze Trade"
- Confirm win / loss ratio and probability of win on Analyze page

Further Applications

- Strategy: Compare Advantage Ratios
 - Trade A has Advantage Ratio A; Trade B has Advantage Ratio B
 - Rule:
 Prefer Trade A over Trade B *if* Ratio A is greater than Ratio B
- Further Applications (see appendix)
 - Confirming Advantage Ratio remains positive after *slippage*
 - Comparing trades at different strikes, dates, volatilities
 - Tracking trades, using Advantage to decide when to exit

Appendix: Equity Curve Simulation

Single Equity Curve Simulation

- **Start** with fixed equity in account
- For each successive component trade: Invest with a given win/loss ratio (namely, a fixed win dollar amount, and a fixed loss dollar amount)
- For each trade, compute incremental P/L
 - Win the win amount with a win probability, **or**
 - Lose the loss amount with loss probability
 - For each trade, add or subtract incremental P/L to current account value
- After many trades, an equity curve is formed, with a path and a final account value

Single Equity Curve Sim.: Insights

- This is a simulation... Other runs of the simulation will result in **different** curves with **different** paths and final values.
- During the simulation, the equity curve is sometimes above 0 (profits) and sometimes below 0 (losses).
- Sometimes there are streaks of losses and wins.
- Depending on when you stop, equity curves could end at a profit or at a loss.

Multiple Equity Curves on One Plot

- Run and plot multiple individual simulations of individual equity curves.
 - Key: All simulations on a single plot have the same win/loss ratio and same probability of win.
 - Key: For each *different* plot, win/loss = \$40/\$60 is constant, while probability of win changes from simulation to simulation, resulting in different equity curve behavior.

Equity Curves: Losing Cases (57%)

MAX Value 121 Win / Loss = \$40 / \$60 🛶 0.66 Probability of Win = 57%, Prob. Of Loss = 43%When win with prob 57%, then make \$40, when lose with prob 43%, then lose \$60. All equity curves end (far) **below** initial value,

MIN Value

Equity Curves: Mostly Even Cases (60%)

Equity Curves: Many Gaining Cases (61%) Win / Loss = \$40 / \$60 = 0.66 Probability of Win = 61%, Prob. Of Loss \leq 39% When win with prob 61%, then make \$40, when lose with prob 39%, then lose \$60. More equity curves end above initial value than below initial value. B4 MIN Value

Equity Curves: Mostly Gaining Cases (63%)

Equity Curves: Leading to a Strategy

- Question: Comparing plots, in which simulations do most of the equity curves remain profitable during trading and end with profits?
- Strategy: Choose a win/loss ratio and probability of win combination that has a high proportion of profitable equity curves.
- **Tactic**: Use Advantage math to **compute** minimum probability of win needed for the given win/loss ratio.
- Example: Use Advantage math, for win/loss = 40/60 = 0.66, given C=0.1, needed/minimum probability of win is 0.62.

Multiple Equity Curve Simulations: Insights

- Profitability is more likely (but not guaranteed) using the "right" combination of win / loss ratio and probability of win.
- Many traders say

This trade has a good risk/reward (loss / win) ratio

but now we know this statement is *incomplete* without also stating the associated probability of win, to characterize the likely equity curve shape.

Equity Curve Simulations: Practical Implications

- You are *not* guaranteed intermediate or terminal equity curves values, *even if* probabilities are in your favor.
- Unfortunately, your own equity curve may be one of the few losing equity curves among many other possible winning equity curves.

Appendix: Math

Adapted from David Sepiashvili, *How to Best Evaluate System Performance*, Futures, March 2005

Definition of Terms: Win, Loss

Total Winnings: Among a large number of trades, the total *dollar* amount of profits.

Total Losses: Among a large number of trades, the total *dollar* amount of losses.

W = **Average Win**: Among a large number of trades, the total dollar amount of winnings, divided by the number of profitable trades (NW)

L = Average Loss: Among a large number of trades, the total dollar amount of losses, divided by the number of losing trades (NL)

For a trading system, **Win / Loss Ratio** = (Average Win / Average Loss) = (W/L)

Definition of Terms: Probabilities

- **NT** = Total number of trades, in a trading system
- **NW** = Number of trades that resulted in a win
- **NL** = Number of trades that resulted in a loss
- **TW** = Total winnings = NW * W
- **TL** = Total losses = NL * L
- PW = Pr(W) =
 Probability of a win = NW / NT
 so NW = PW * NT
- PL = Pr(L) = Probability of a loss = NL / NT
 so NL = PL * NT

PW + **PL** = 1 (*only* wins or losses are possible) 42

Advantage Formula: Background

Formula: (TW - TL) / TL = C

where:

- TW = Total winnings,
- TL = Total losses,
- C = "Advantage" preference

English: A trading system is measured by its winnings in excess of losses, normalized by losses. "C", the *advantage*, is a trader's economic preference.

Adapted from David Sepiashvili, *How to Best Evaluate System Performance*, Futures, March 2005

Advantage Formula: Algebra

(TW – TL) / TL = [TW / TL] - 1 = [(NW*W) / (NL*L)] - 1 = [(PW*N*W) / (PL*N*L)] -1 = [(PW*W) / (PL*L)] -1 = [(PW/PL) * (W/L)] - 1 = [(PW/(1-PW)) * (W/L)] - 1 = C

Advantage Forumla: Solve for PW

Solve for PW, given (W/L) and C in: (TW – TL) / TL = [(PW/(1-PW)) * (W/L)] - 1 = C

Set P = PW {shorthand}
[
$$(P/(1-P)) * (W/L)$$
] - 1 = C
 $(P/(1-P)) * (W/L) = (C+1)$
 $(C+1) * 1/(W/L) = P/(1-P)$

Set S = (C+1) * 1/(W/L) S = P/(1-P), (1-P)S=P, S-PS=P, S=P+PS, S=P(1+S), P=S/(1+S)

PW = S / (1+S)

Using Advantage Algebra

- Set Advantage: Assume you seek an Advantage of +10%, so set C = 0.1
- Free Variables: Since C is now fixed ("bound"), there are two remaining free variables: W/L and PW Advantage math relates one given the other.
- **Application Summary**: Invest in trades whose *market* probability of winning [Pr(W) market] is greater than *Advantage calculated* probability of winning [Pr(W) needed], for the given win/loss [W/L] ratio, at a constant Advantage C.
- A constant Advantage C curve represents all pairs of (W/L) and Pr(W).

Appendix: Constant Advantage Curves

Constant-Advantage Curves: Graph

Constant-Advantage Curves: Analysis

- Higher win/loss ratios correspond with *lower* probabilities, across all Advantage curves
- For a given probability, higher advantages demand higher win/loss ratios
- For a given win/loss ratio, higher advantages demand higher probabilities
- Advantage curves C < 0 (negative Advantage) are
 - likely to produce losses over the long-term,
 - are not shown on the graph, and
 - **should not** be traded.

Appendix: Further Applications

Advantage Ratio: Slippage

- Confirm Advantage Ratio at **mid-price**
- Confirm Advantage Ratio at **likely fill price** (toward natural price)
- Confirm Advantage Ratio after commissions

Advantage Ratio: Comparing Trades

- Confirm Advantage ratios after modifying trade parameters (from options pricing model), e.g.,
 - Strike price
 - Volatility
 - Expiration date
 - Closing date before expiration

Advantage Ratio: Tracking and Closing Trades

- Approach: Exit trade by comparing *marketplace* probability of win on trade **opening** day to **successive** days' *market* probabilities.
- Method
 - Open trade with Advantage Ratio above 1.
 - Define probability of win, when opening, in the marketplace as P0.
 - For each successive trading day t, compare probability of win in the marketplace Pt to P0: Pt/P0.
- Examples
 - Exit when Pt/P0 is ½ of P0. Note: Ratio of ½ is a preference.
 - Exit when "high probability" 80% trade becomes "even" 50% probability
